Abstract

With regard to the separating isosurface of two classes of objects in two-dimensional space, the transition from curvilinear to rectilinear is documented. OpenCV and Marching Squares were used to calculate the data that were used for illustrations in this paper.

1 Introduction

A balance between high variance (curvilinearity) and high bias (rectilinearity) is to be had.

Marching Squares works as a radial (spherical) isosurface generator, as well as a linear (planar) isosurface generator – it all depends on the grid resolution. The data generated by Marching Squares are the line segments that separate the two classes, as well as triangles for the area of each class. Classifying a test point is a matter of ray-triangle intersection, which can be accelerated using a Bounding Volume Hierarchy or quadtree data structure.

OpenCV was used to downsize the bitmap image. OpenCV could also have been used to transform the bitmap image via blur, sharpen, or whatnot – this visual method practically begs for such experimentation.

So what? Is this useful, and if so, is it widely-known?
